Monte Carlo study of the Pure and Dilute Baxter-Wu model

Nir Schreiber and Joan Adler
Physics Department, Technion, Israel Institute of Technology, Haifa, Israel, 32000

Abstract. We studied the pure and dilute Baxter-Wu (BW) models using the Landau-Wang (LW) sampling method to calculate the Density-Of-States (DOS). We first used the exact result for the DOS of the Ising model to test our code. Then we calculated the DOS of the dilute Ising model to obtaining a phase diagram, in good agreement with previous studies. We calculated the energy distribution, together with its first, second and fourth moments, to give the specific heat and the energy fourth order cumulant, better known as the Binder parameter, for the pure BW model. For small samples, the energy distribution displayed a doubly peaked shape. Finite size scaling analysis, however, showed a power-law decay of the right peak with the ratio $\phi_+ / \nu = 0.531 \pm 0.048$. The energy distribution yielded the expected BW $\alpha = 2/3$ critical exponent for the specific heat. The Binder parameter minimum appeared to scale with lattice size $L$ with an exponent $\theta_B$ equal to the specific heat exponent. Its location (temperature) showed a large correction-to-scaling term $\theta_L = 0.248 \pm 0.025$. For the dilute BW model we found a clear crossover to a single peak in the energy distribution even for small sizes and the expected $\alpha = 0$ was recovered.

1. Introduction

The two-dimensional Ising model has received such widespread attention as the paradigm system for phase transitions, that one sometimes says that a certain system is the “Ising model” of a class of problems. While it is clearly special, it is not the only two dimensional model of phase transitions with an exact expression for its free energy. Its critical behavior is, in fact, rather atypical relative to many other two-dimensional systems and even to the three-dimensional Ising model, especially in the specific heat, where its critical exponent, $\alpha$, is zero. The nature of the corrections-to-scaling in the spin 1/2 Ising model is also very different to that of many other interesting systems.

Another spin system, now known as the Baxter Wu (BW) model, was solved by R.J. Baxter and F.Y. Wu [1, 2]. Spins $\sigma_i = \pm 1$, are situated on the triangular lattice and interact via a 3 spin interaction,

$$\mathcal{H} = -J \sum_{i,j,k} \sigma_i \sigma_j \sigma_k,$$

(1)

where $i, j$ and $k$ are the vertices of a triangle as shown in Fig. 1. $J > 0$ is the ferromagnetic coupling between nearest neighbor spins. The BW model exhibits a second order phase transition with its critical temperature ($T_c$) given by $2J/kT_c = \ln(1+\sqrt{2}) = 2.26918...$, (the same numerical value as for the Ising model on the square lattice). The specific heat critical exponent is equal to the correlation length exponent, $\alpha = \nu = 2/3$. Series-expansion results [3], gave the conjectured magnetization exponent of $\beta = 1/12$ and a susceptibility exponent of $\gamma \approx 1.17$ [4]. The latter confirmed the prediction of $\gamma = 7/6$ from the well known scaling relation $\alpha + 2\beta + \gamma = 2$ [5, 6]. Real Space Renormalization Group methods have also been used [7, 8] to study the pure model, and the critical eigenvalues obtained gave critical exponents consistent with series-expansion and exact results. An exact form for BW corrections-to-scaling was found by Joyce [9] who conjectured that the spontaneous magnetization varied as $M = t^\beta \left( f_0(t) + t^{2/3} f_1(t) + \cdots \right)$ with analytic functions $f_0$, $f_1$ of the distance $t = (T - T_c)/T_c$. Adler and Stauffer confirmed this with series and Metropolis Monte Carlo estimates [10].

\caption{The energy of a given configuration is the sum of all interacting triangles formed by nearest neighbor spins}
\end{figure}
Dilute Ising models are also somewhat famous, but for rather different reasons, as they have been the source of a great deal of controversy. Presumably because of the anomalous specific heat structure in the pure case, numerical work in the dilute regime, especially near the pure limit is painful, and although a majority of authors (see e.g. Roder et al, [11]) have claimed that the controversy is resolved in favor of SSL theory [12, 13, 14], more study is useful.

The annealed dilute BW model was studied by Kinzel, Domany and Aharony[15] who showed from this exploration that its dominant critical behavior is in the universality class of the four state Potts model, although the Potts model has logarithmic correction terms for this case. Domany and Riedel [16], argued the same for the pure BW model by means of symmetries of the Landau-Ginzburg-Wilson Hamiltonian. (Note that there are first order fixed points in the neighborhood of these models). The quenched dilute BW model was studied by Landau and Novotny [17], who found a substantial change in the critical behavior of the specific heat [18] for an impurity concentration of $1 - x = 0.1$. They also conjectured that the zero temperature threshold concentration above which no long-range order could be seen was about $x_c \simeq 0.71$. (See also results from a cluster-algorithm study of this system [19]). More recent calculations [20, 21] showed that the value of $x_c$ is even higher ($x_c \simeq 0.755$), and is bounded by $x_{c,\text{low}} = 0.710 \pm 0.001$ and $x_{c,\text{high}} = 0.784 \pm 0.004$. This is substantially above the value for Ising models where $x_c$ is simply the percolation threshold of the corresponding lattice, which is rarely above 0.5.

Recently Landau and Wang [22] proposed a very efficient algorithm for calculating the DOS, (i.e. the degeneracy of any level in energy space), $g(E)$, for Ising models and some related systems. To explore the issues of both pure and dilute BW models further, and to see how its different particulars of large $\alpha$ and corrections to scaling emerge from the calculation of the DOS, we have chosen to apply the LW algorithm to both the pure and quenched dilute BW models, and to study the behavior of the energy distribution and related moments [23, 24] using the simulated DOS. The DOS of the pure and dilute Ising models was studied for comparison purposes.

In the next section we discuss the LW algorithm. In section 3 we present a comparison of an exact calculation of the DOS for the Ising model [30] with simulations using LW and give some results for the dilute Ising case. In section 4 we give in detail our results for the pure BW model, and in section 5 the results for the dilute BW model are presented. Finally we discuss the implications of our results in section 6.

2. The simulation method

Conventional Monte-Carlo (MC) methods [25, 26, 27] generate the canonical energy distribution at a given temperature $T_0$. It is usually narrowly peaked around this temperature. The need to perform multiple simulations in order to obtain thermodynamics in a large range of temperatures requires a large computational effort. Other methods based on histogram accumulation [24, 28] approximate the distribution
by the energy histogram at $T_0$. This distribution can then be reweighted to give statistics at another temperature. The reweighted distributions, however, are also restricted to a very narrow range of temperatures and suffer from large statistical errors in their tails for temperatures far from $T_0$. The broad histogram method [29] calculates the DOS through the consideration of the average number of visits to any two adjacent energy levels.

Landau and Wang [22] proposed a very efficient algorithm for calculating the DOS, based on the observation that the transition probability between any two energy levels $E_i$ and $E_j$ is proportional to the ratio between the DOS of these states. The energy histogram, $H(E)$, is accumulated at each visit until it becomes "flat" (we have used the condition $|H(E) - \langle H \rangle|/\langle H \rangle \leq 0.05$ for any $E$). By dividing the energy space into different segments, and performing an independent random walk in each segment, one can generate very accurately, in a reasonable amount of CPU time, the DOS of the whole energy space, thus obtaining the canonical distribution at any desired temperature.

3. Ising model results

3.1. The pure Ising model

We began by validating the accuracy of our implementation of the LW algorithm against exact results for the Ising model on the square lattice with no impurities. A detailed comparison was made for the case of $L = 32$. The partition function for the Ising model on a lattice of length $L$ can be written as a low temperature expansion

$$Z_N = e^{2KN} \sum_{\ell} g_\ell x^{2\ell},$$

(2)

where $N = L \times L$ is the number of spins, $K = J/kT$ is the reduced inverse temperature, and $x = e^{-2K}$ is the low temperature variable. Each energy level can be labeled (relative to the ground state energy $-2JN$) by $E_\ell = 4\ell \ell (\ell = 0, 2, 3, ...N - 2, N)$, so that $g_\ell$ is its corresponding DOS. Beale [30] used an extension of Onsager's solution [31], to give the exact expression for the partition function on a finite lattice [32], and extracted the DOS coefficients from the expansion (2). In Fig. 2 we plot our results on top of Beale's expression for the case of $L = 32$ and see no deviations between the exact and the simulated data within the resolution of the figure.

Further results from the pure Ising simulations will be introduced for comparison purposes in section 4.

3.2. The dilute Ising model

We continued the validation process by studying the dilute Ising model. at a lattice size of $L = 22$ only. The Hamiltonian for the dilute Ising model may be written as

$$\mathcal{H} = -J \sum_{i,j} \epsilon_i \sigma_i \sigma_j,$$

(3)
Figure 2. Simulated and exact \( g(E) \) for a 2\( d \) Ising model (32 \times 32 lattice). Simulation results are in good agreement with the exact calculation [30]. The relative error is given in the inset.

where the random disorder variables \( \epsilon_i \) take the values 0 and 1, such that their configurational average is equal to a dilution of \( 0 < x < 1 \). We considered the position of the specific heat maxima, \( T_{C_{\text{max}}} \), for different nominal concentrations centered around the values \( x = 0.8 \), \( x = 0.9 \), and \( x = 0.95 \), as indicated in Fig. 3. It is clearly seen that for large concentrations (\( x \geq 0.9 \)) the circles tend to a continuously critical line, slightly shifted from the solid line. The shift results from the fact that only one small lattice size was used. For smaller concentrations there is a large dispersion of the circles and the data is unreliable. As shown in Fig. 4, the specific heat maximum becomes broader with decreasing concentration and is hard to locate precisely. The reason for this is when Lowering \( x \) isolated clusters which rarely interact with each are formed, and hence energy fluctuations become smaller. For a concentration of \( x = 0.75 \) they are also nearly constant and therefore no pronounced peak can be identified. In the absence of analytic results, the location of our points close to earlier estimates validates both our dilute code and our analysis methods.

4. The pure Baxter-Wu model

We calculated the DOS for the BW model using lattice sizes \( L \) ranging from 6 to 120, with periodic boundary conditions being imposed. For each lattice size the data was collected separately for each energy segment and then was combined to give the density of states for the entire energy landscape. We averaged over nine different runs for \( L = 30 \), and saw that the fluctuations were three order of magnitude smaller then the measured quantity (\( \ln g \)), so that we neglected these fluctuations and for each lattice size we executed a single run per segment only. By symmetry, for any state with negative
Figure 3. Critical line $T_c(x)$ in the $T$-$x$ plane of the dilute Ising model. Small energy fluctuations for $x \leq 0.8$ make it hard to reliably determine $T_{c=\infty}$. The asterisks represent results from MC Renormalization Group calculations [33] and the solid line is the prediction $T_c(x) = \{\tanh^{-1} [e^{-1.45(x-x_c)}]\}^{-1}$, converging to the value of $x_c = p_c = 0.593$ [34].

Figure 4. The specific heat of the dilute Ising model for different concentrations on a $L = 22$ lattice. For $x = 0.75$ there is no pronounced peak present.

energy, there exist a state with positive energy, so that it was sufficient to carry out the random walk only for non positive energies. (A similar argument holds for the Ising model). Plots of the internal energy, specific heat, free energy and entropy are given in Fig. 5.

Early simulations [17] showed the formation and motion of domains around the ferromagnetic and ferrimagnetic ground states, due to the special connectivity of the BW model, causing low frequency large energy fluctuations. These fluctuations made
Figure 5. Calculation of thermodynamic functions for the pure BW model on an $L = 54$ lattice: (a) Internal Energy, (b) Specific Heat, (c) Entropy and (d) Free energy. The specific heat displays a very clear pronounced peak at the transition point.

the impression that the system was in a metastable state, thus indicating a first order transition. In Fig 6 we examined the energy distribution at $T_{C_{\text{max}}}$ and found a doubly peaked curve. The system appears to fluctuate between these two peaks denoted by $E_-$, corresponding to an "ordered" state (more negative) energy, incorporating small clusters, and $E_+$, corresponding to a "disordered" state energy incorporating large clustering. A plot of the distribution for the Ising model both at $T_{C_{\text{max}}}^{\text{Ising}}$ and at $T_{C_{\text{max}}}^{\text{BW}}$ shows clearly sharp single peaks centered approximately at the critical energy $U_c = -\sqrt{2}J$ (Fig. 7). This supports the uniqueness of the distributions in Fig 6. We performed finite size scaling of the positions (energies) of the peaks according to

$$|E_\pm(L)| = |U_c| + E_{0\pm}L^{-\phi_\pm/\nu},$$

where $E_{0\pm}$ are positive amplitudes and $\phi_\pm$ are the scaling exponents of the "disordered" and "ordered" energies, respectively. We see in Fig. 8 the variation of $\ln E_+$ with $\ln L$. The scatter of the "ordered" energy data was too large, probably due to systematic deviations caused by the division of energy space into different segments, and therefore not presented. A least square fit to the "disordered" energy data gave $\phi_+/\nu = 0.531 \pm 0.048$.

A comparison between the DOS of the Ising model and the BW model (Fig. 9) shows a significant difference between the two models. Although they have approximately the same number of different energy levels ($N - 1$ for Ising and $N - 3$ for BW), the function $\ln g$, appears to be concave everywhere in the interval $[-2, 0]$ for the Ising model, while, for the BW graph this may not be so. This suggests an explanation for the appearance of the two peaks which is also consistent with the fact that they have the same height: The condition that the distribution will have extrema is satisfied by

$$d(\ln g)/dE = 1/kT.$$
Figure 6. Critical distribution calculated at $T_{c_{\text{max}}}$ for the pure BW model. The lattice sizes are denoted by arrows. The $L = 120$ data suffers from the systematic errors resulting from the DOS calculations for large systems.

Figure 7. Energy distributions at $T^{\text{Ising}}_{c_{\text{max}}} = 2.28948 J / k_B$, at $T^{\text{BW}}_{c_{\text{max}}} = 2.27549 J / k_B$ and at the exact transition point $T_c$ on the same lattice with $L = 54$. The numbers in parenthesis denote: (1) Ising at $T^{\text{BW}}_{c_{\text{max}}}$, (2) BW at $T_c$, (3) Ising at $T^{\text{Ising}}_{c_{\text{max}}}$, (4) BW at $T^{\text{BW}}_{c_{\text{max}}}$. Note the distribution at the exact transition point (2) with the ratio of $r \approx 4$ between the pronounced peak on the left and the "hump" on the right [24]. The asterisk denotes their common critical energy $U_c = -\sqrt{2} J$.

If, at $T_{c_{\text{max}}}$, Eq. (5) has locally, a solution $f_1(E) = E / k T_{c_{\text{max}}} + C_1$ tangent to $\ln g$ at $E_-$ and $E_+$, and another solution $f_2(E) = E / k T_{c_{\text{max}}} + C_2$ tangent to $\ln g$ at $U_c(L)$ (at the shifted critical energy, or the minimum between the peaks), then the distribution will have two peaks with equal height satisfying

$$p(E_-) = p(E_+) = e^{C_1},$$

(6)
as seen in Fig. 6. This is essentially a finite size effect and should be recovered by a large enough sample, to give an "Ising like" concave everywhere DOS function, and a single peaked distribution as its consequence.

We further calculated the specific heat for each lattice size and then plotted its maximal value $C_{\text{max}}$ versus $L$. We see in Fig. 10 a very nice agreement between the calculated data and the second order ansatz $C_{\text{max}}(L) \propto L^{\alpha/\nu}$, with $\alpha/\nu = 1$, even for very small lattices ($L = 6$).

When we calculated the Binder parameter, $B$, (whose plot as a function of temperature is given in Fig. 11), we saw a sharp inverse peak that usually occurs in first order transitions [23, 24]. This led us, at first, to incorrectly assume that this peak remains finite for an infinite system and tends to the limit [23] $B_{\text{min}} = 1 - 2(E_+^4 + E_+^4)/3(E_+^2 + E_+^2)^2$ which was extrapolated from the scaling of the Binder parameter with the inverse volume $L^{-2}$ (see Fig 13). We know from first order finite size scaling theory that the position of $B_{\text{min}}$ (denoted by $T_{B_{\text{min}}}$) also scales with the inverse volume. Neglecting small lattices, we performed finite size scaling for the position of the Binder parameter minimum and obtained a very precise (though quite unreliable, as can be seen in Fig. 14) estimate for the infinite volume transition point of $T_c = 2.2696 \pm 0.0004$.

It is important to note that since the transition is continuous and therefore no ordered and disordered states coexist at the transition point, the critical probability distribution in the infinite volume limit is expected to be single peaked, causing $B_{\text{min}}$ to eventually vanish with some exponent and the Binder parameter to take the trivial value of $2/3$ also at the critical point. It was therefore convenient to repeat finite size scaling for $B_{\text{min}}$ according to

$$B_{\text{min}} = \frac{2}{3} - B_0 L^{-\theta_\nu},$$  

(7)
Figure 9. DOS of BW and Ising models on the $L=54$ lattice. The function $\ln g$ appears to be concave "everywhere" in $[-2, 0]$ for the Ising model, while this may not be so in the BW case. A plot of $\ln g(E)$ versus $E$ for a larger BW system ($120 \times 120$) is given in the inset.

Figure 10. Scaling of the specific heat maxima with the length $L$ for the pure BW model. The predicted $C_{\text{max}}(L) \propto L$ behavior is indicated by a solid line.

where $\theta_B$ is an exponent yet to be determined. In Fig. 15 we see the variation of the inverse distances $t^{-1}_{C_{\text{max}}} \equiv (T_{C_{\text{max}}} - T_c)^{-1}$ and $t^{-1}_{B_{\text{min}}} \equiv (T_{B_{\text{min}}} - T_c)^{-1}$, correspond to the positions of the specific heat maxima and Binder parameter minima, respectively, with $L$. A least square fit gave a slope of $1.529 \pm 0.039$ for the specific heat temperature and $1.748 \pm 0.025$ for the Binder parameter temperature. From [28]

$$T_{C_{\text{max}}} = T_c + A_0 L^{-\nu} \left( 1 + A_1 L^{-\omega_1} + \cdots \right),$$  
(8)

$$T_{B_{\text{min}}} = T_c + B_0 L^{-\nu} \left( 1 + B_1 L^{-\theta_1} + \cdots \right),$$  
(9)

where $\omega_1$ and $\theta_1$ are correction exponents and $A_0, A_1, B_0$ and $B_1$ are amplitudes
Figure 11. The Binder parameter for the pure BW model versus temperature, for various lattice sizes, from top \((L = 120)\) to bottom \((L = \infty)\) in descending order. The Binder parameter is seen in the figure to display an inverse peak whose depth decreases as the system size increases. The infinite volume upper bound \(B_{\text{min}}\) is the intercept that is plotted in Fig. 13.

Figure 12. Temperature variation of the Binder parameter for the Ising model, from top \((L = 60)\) to bottom \((L = 24)\) in descending order. The data in the inset is given for the same lattices on a larger scale. The data for \(L = 54\) is calculated using simulated DOS. All other data is exact.

determined from simulations, it is evident that \(T_{B_{\text{min}}}\) displays a large correction-to-scaling term \((\theta_1 \simeq 0.25)\), in contrary to the resulting \(1/\nu\) scaling from the \(T_{C_{\text{max}}}\) fit, which is in fair agreement with the exact \(3/2\) value, and which is also consistent with the scaling of \(C_{\text{max}}\). It is also evident, however, from Fig. 16 and Eq. (7), that \(\alpha\) and \(\theta_B\) have the same value. Similar exact and simulational calculations of the Binder parameter for the Ising model on the same temperature scale (Fig. 12) showed much
Figure 13. Scaling of the Binder parameter minimum, $B_{\text{min}}$, with the inverse volume for the pure BW model.

Figure 14. Scaling of $T_{B_{\text{min}}}$ with the inverse volume of the system for the pure BW model.

broader and less deep minima at $T_{B_{\text{min}}}$, suggesting that these minima vanish with an exponent $\theta_B$ larger than the BW exponent.

5. The dilute BW model

Let us consider now the ferromagnetic BW model with quenched impurities. The Hamiltonian is given by

$$H = -J \sum_{i,j,k} \epsilon_i \epsilon_j \epsilon_k \sigma_i \sigma_j \sigma_k.$$  (10)
Figure 15. Scaling of the inverse distances $t_{C_{\text{max}}}^{-1}$ and $t_{B_{\text{min}}}^{-1}$, with $L$, for the BW model. The larger slope of the Binder parameter position’s fit, may be a result of the large correction term $\theta_1$ (see Eq. 9). The specific heat data was shifted for ease of reading.

Figure 16. Scaling of the quantity $(2/3 - B_{\text{min}})^{-1}$ and the specific heat maximum $C_{\text{max}}$, with $L$, for the BW model.

We studied systems with lengths $L$ between 18 and 36. We kept concentrations of $x = 0.8$ for $L = 18$ and of $x = 0.9, 0.95$ and $x = 0.97$ for $L = 33$, fixed, and let them vary around $x = 0.9$ for $L = 33$. The data for $L = 24$ was calculated for concentrations varied around different values from $x = 0.85$ to $x = 0.97$. In Fig. 17 we compare the DOS of the pure and dilute BW models. The apparent crossover to a manifestly clear second order transition may give rise again to a concave ”everywhere” form of $\ln g$, already seen for the Ising model in Fig. 9. The energy levels differ now only in the amount of $2J$ and can take even or odd values for the same lattice size, depending on the vacancy distribution. We then performed a calculation similar to that made above for the dilute
Figure 17. DOS for a pure (upper curve) and for a dilute (lower curve) BW model with \( x = 0.9 \), on an \( L = 36 \) lattice.

Ising model, of \( T_{c_{\text{max}}} \), to obtain the \( T_c(x) \) critical line on a lattice with \( L = 24 \), and then fitted the high concentration data into a continuous (dotted) line (Fig. 18). All the data except for the \( L = 18 \), which was, as for the dilute Ising model, unreliable because of high dilution, fell very well on the dotted line. The three points measured for \( L = 33 \) were averaged, and together with the data measured for a fixed concentration on other lattice sizes, we performed a rough finite size scaling for the specific heat at a concentration of \( x = 0.9 \).

Novotny and Landau [17] predicted \( \alpha/\nu \approx 0 \) for a concentration of 0.9. Our results, presented in Fig. 20 also indicate, at least qualitatively, a significant change in \( \alpha \). Since spatial correlations become smaller and hence \( \nu \) becomes smaller, the value of \( \alpha \) substantially decreases, thus indicating an "Ising like" singularity at the finite lattice transition point. Moreover, the Harris criterion for the diluted case is hereby confirmed. Another question of interest was the influence of vacancies on the nature of the transition. In order to make a statement regarding this question we plotted in Fig. 21 the energy distribution for different concentrations. We see clearly and unsurprisingly that lowering the concentration causes the doubly peaked distribution to vanish and become a single peaked one with a narrower width centered away from \( U_c \). It may then be plausible to say that in contrast to energy fluctuations which become negligible at sufficiently low concentrations, magnetic fluctuations increase with increasing dilution and the transition is manifestly 2nd order.

6. Conclusions

Our simulations have shown that the LW sampling is a very accurate algorithm. The overlap between the simulated and exact density of states from Fig. 2, and the
Figure 18. Normalized critical temperature for different concentrations on a $L = 24$ lattice size for the dilute BW model.

Figure 19. Normalized critical temperature for fixed concentrations on different lattice sizes for the dilute BW model.

thermodynamic quantities resulting from the calculated $g(E)$, which yield reasonable quality critical data, provide good evidence for this.

Our results show that the pure Baxter-Wu model is strongly influenced by finite size effects and corrections to scaling. The scaling of the specific heat maxima is in excellent agreement with the second order form $C_{\text{max}} \propto L^{\alpha/\nu}$, even for small lattices, and no correction terms are observed. The Binder parameter, however, display large minima for small samples, thus incorrectly could be thought of as a "first order" scaling field. It is an "irrelevant" field in the sense that it gives no additional information about the universal exponents $\alpha$ and $\nu$, but rather vanishes with an exponent $\theta_B$. This exponent is also evident in the Ising model and is presumably larger for this model. The
Figure 20. Finite size scaling of $C_{\text{max}}$ with $L$ for the pure and dilute BW model. The data for the dilute model reveals an $\alpha$ exponent close to zero.

Figure 21. Critical energy distribution for various concentrations and critical temperatures, calculated on a $L = 24$ lattice. The numbers in parenthesis denote: (1) $x = 0.85$; $T_c = 1.74926$, (2) $x = 0.95$; $T_c = 1.93379$, (3) $x = 0.97$; $T_c = 2.07671$, and (4) $x = 1$ (pure); $T_c = 2.29164$. The distribution is seen to become sharper and narrower when the concentration is reduced.

vanishing inverse peak in both models states that the energy distribution approaches a $\delta$ function in the thermodynamic limit, although it is essentially non-Gaussian. The doubly peaked shape of the latter is rather peculiar. One would usually expect a single peaked distribution which becomes narrower, the closer to criticality one is. This shape is essentially a finite size effect due to the large fluctuations between the ferromagnetic and ferrimagnetic clusters formed in the vicinity of the transition point, and will eventually vanish in the thermodynamic limit. The LW method is also very successful when applied
for the dilute BW model even for small lattices, both in terms of the critical isotherm in temperature-concentration plane, and probability distribution. A crossover to a single peaked critical distribution is clearly seen when decreasing the concentration of spins, and a single peaked distribution is evident at a concentration of $x = 0.85$. This is a result of the formation of isolated domains causing relatively small energy fluctuations around the critical energy.

It would be interesting in the future to use larger lattices to confirm our explanations of the finite size problems. The relatively high accuracy of the LW method for small dilute systems could be applied in the future to study disorder in other models.

Acknowledgments

We thank Prof. D. Stauffer, Prof. D.P. Landau, Prof. M.E. Fisher and Prof. W. Janke for useful comments and suggestions. We would like to thank E. Warszawski and I. Klich for helpful discussions. We thank the BSF for generous support throughout this project. The financial support of the Technion is also gratefully acknowledged.
